ABSTRACT: Herein, we report on the precise design of a modular fusion protein amenable to the construction of nanocapsules by nanoprecipitation. The central squid suckerin-derived peptide block provides structural stability, whereas both termini from silk fibroins make the modular protein highly soluble at physiological pH, a critical requirement for the nanoprecipitation process. With this molecular design, nanocapsules consisting of suckerin-silk fusion protein shells and hexadecane or miglyol cores with sizes in the range 190 – 250 nm are straightforwardly built.

Polymer nanocapsules are progressively emerging as promising candidates for drug delivery applications thanks to their potential to improve targeting, drug efficiency, reduced side effects, their aptitude to co-deliver multiple drugs or their ability to cross physiological barriers including the cell membrane.^{1,2} Owing to specific physico-chemical and biological properties including inherent biocompatibility, low immunogenicity, biodegradability, complete control of the (amino acid) sequence, or the suitability to diverse functionalization with bioactive domains, proteins are a particularly advantageous class of building blocks for the construction of nanocapsules.^{3,4} The most common proteinaceous nanocapsules for encapsulation of drugs are self-assembled protein nanocages, such as ferritin or vault nanostructures, which are made of protein subunits that self-assemble into nanoscaled cages with precise geometry.³ While this biological approach leads to ordered protein nanostructures with exquisite control over their geometry and near monodisperse size distributions, it is unfortunately limited to specific protein building blocks that self-assemble via precisely-defined protein-protein interactions of the subunits.⁵ Alternatively, the construction of proteinaceous nanocapsules can be undertaken by means of chemical or physico-chemical approaches. The prevalent routes rely on multi-step template driven strategies such as layer-by-layer technique⁶, complex coacervation emulsification technique⁷, or interfacial reactions of proteins in water-in-oil miniemulsion systems.^{8,9}

Nanoprecipitation is a simple and easy-to-use "bottom-up" strategy typically relying on the supersaturation of a hydrophobic solute (such as an oil, first dissolved in a water-miscible solvent) upon addition of water, and has lately emerged as a general and modular method to generate polymer nanocapsules with a precise control of the dimensions and the physico-chemical properties. The first step of nanoprecipitation is to establish phase diagrams and to identify the domains of interest, e.g. Ouzo and Surfactant-Free MicroEmulsion (SFME) regions.¹⁰ This information can then be used to establish conditions of solvent shifting so that the solute is spontaneously emulsified and forms submicronic templates, onto which hydrophilic polymer chains (initially dissolved in the aqueous phase) quantitatively precipitate to grow a robust polymer shell. Following this route, oil-filled nanocapsules have been constructed from a range of vinyl-based polymers^{11,12} and polysaccharides¹³. However, to the best of our knowledge, the preparation of protein-based nanocapsules by nanoprecipitation has not been reported yet.

A recently discovered family of structural proteins, suckerins, has shown promising potential for biomedical applications^{14,15} (including

as therapeutics carriers). Suckerins are modular, block copolymer-like structural proteins that constitute the hard sucker ring teeth of squids and cuttlefish.¹⁶ They consist of 10-12 amino acid-long modules forming β -sheets that are interspersed by longer, mostly amorphous domains^{17,18} (although protein NMR experiments indicate that short peptides in these domains can also form β -sheet secondary structures^{19,20,21}), resulting in mechanically-robust materials with good processability.²² Another important biochemical feature of suckerins is their high Histidine (His) amino acid content (ca. 10 mol.%). Because of the pKa (ca. 6.0) of its imidazole side-chain, His is protonated under mild acidic conditions, which not only enhances the solubility of suckerins in water but also facilitates endosomal escape via the proton-sponge effect.¹⁴ While suckerins can be readily produced recombinantly in *E. coli* with full control of the amino acid sequence,²³ they usually aggregate in the inclusion bodies during expression because of the relatively high content of hydrophobic residues, requiring subsequent treatment with high concentration urea in order to solubilize them.²³ Moreover, although purified recombinant suckerins are soluble at acidic pH, their solubility significantly decreases in aqueous buffers around pH 7. This pH-dependent solubility is beneficial to fabricate films or other solid materials^{21,22} but may constitute a barrier for obtaining nanocapsules by nanoprecipitation. Indeed, the efficiency of the process is generally compromised when pH values are below 5 or above 10,²⁴ and self-assembly or aggregation of the proteins is not desirable before solvent shifting.

In this context, we aim herein at developing simple nanoprecipitation routes to nanocapsules involving suckerin-based recombinant proteins and water/acetone/oil ternary systems. Starting from previously reported recombinant proteins from suckerin-19, we then describe how engineering of fusion suckerin proteins with enhanced solubility in water can be achieved by fusing a silk-derived solubility tag to a central suckerin domain, thereby affording the production of proteinaceous materials with aqueous solution behavior at pHs compatible with a solvent shifting procedure (see Figure S1). We further establish these recombinant suckerin-silk fusion proteins as promising modality to produce protein-based functional nanocapsules through nanoprecipitation in a straightforward manner.

We first tested suckerin-19 in nanoprecipitation assays. The two amino acids with ionizable side-chains in suckerin-19 are tyrosine (Tyr) and His (ca. 15% and 10% of the protein composition) residues.^{19,20,21} These residues possess R groups with pKa's around 6 (imidazole of His) and 10 (hydroxyl of Tyr). The protein net charge is thus nil in the pH range between 6 and 10 so the chains tend to

Figure 1. (a). (top) Modular representation of suckerin silk fusion protein (NT-SUP-CT). NT, suckerin peptides, and CT sequences definitions and sequences are given in Tables 1 and 2; (bottom) schematic representation of micellar-like soluble structures generated in water thanks to the hydrophilicity of N- and C-termini domains (adapted after Ref. 28). (b) SDS-PAGE of NT-SUP-CT fusion protein. Bio-Rad Precision Plus Protein Standards Dual Color was used as a reference ladder. (c) CD spectra of NT-SUP-CT at varying temperatures (blue: 20°C, red: 40°C, black: 60°C). (d) MALDI-ToF spectrum of NT-SUP-CT fusion protein. The main m/z peak at 33 kDa corresponds to the expected MW of NT-SUP-CT fusion protein. Peak at 16.5 kDa corresponds to the doubly charged ($z = 2$) species. (e) DLS spectra of suckerin silk dissolved in a 20 mM aqueous buffer at pH 7.4 and a concentration of 3.5 mg/ml.

aggregate (Figure S2). Since acidic pHs (at which suckerin 19 chains are closer to monomeric state, pH = 3) impair the nanoprecipitation process, we first intended to generate nanocapsules through solvent shifting at pH ~ 10 (see DLS of aqueous protein solutions at pH 10, Figure S3). Under such conditions, the solvent shifting procedure yielded ill-defined mixtures of protein capsules together with protein aggregates in the range of a few hundred nanometers as evidenced by TEM analyses (see Figure S4 in supporting information).

We then decided to design a fusion protein containing suckerin peptide domains and exhibiting water solubility in appropriate pH conditions for nanoprecipitation. In a recent study, Andersson et al.²⁵ demonstrated that engineered spider silk proteins (fibroins) could be produced in *E. coli* in soluble form and at remarkably high yield (in the range of 200-300 mg/mL). Like suckerins, spidroins contain a long repetitive, hydrophobic central domain that forms strong β -sheet structures in silk fibres. This domain is flanked by nonrepetitive N-terminus (NT) and C terminus (CT) globular domains, whose roles are to maintain a high solubility of the spidroins in the silk-forming gland of the spider and to trigger aggregation into β -sheet rich structures during silk drawing.^{26,27} Exploiting the NT domain of a spidroin from *Euprosthenops australis* (*E. australis*) and the CT domain of a spidroin from *Araneus ventricosus* (*A. ventricosus*), this group was able to produce proteins and peptides that are notoriously difficult to express in soluble form, including membrane proteins or amyloidogenic peptides.^{28,29} Based on such results, we hypothesized that these NT and CT tags could be fused to suckerins or suckerin

peptides as a way to enhance their solubility near neutral pH. We constructed a fusion protein consisting of central suckerin-derived peptide (SUP) domain flanked by NT and CT tags (NT-SUP-CT) (Figure 1a).³⁰ The SUP domain contains three copies of the peptide module PAATAVSHTHHA that was previously shown to form cross- β functional amyloids³⁰, separated by di-Glycine linkers. Furthermore, to bring chain flexibility to the construct, the β -sheet forming modules were flanked by two copies of the Glycine (Gly) and Tyrosine (Tyr)-rich amorphous peptide GLGGYGGLYGGY, also found abundantly in suckerins.¹⁷

Our results show that NT-SUP-CT fusion protein can be recombinantly expressed in *E. coli* in soluble form, with a high yield of ca. 100 mg/L of recombinant bacterial culture. NT-SUP-CT can be readily purified using nickel affinity chromatography in aqueous buffer without the need of using denaturing agents, and can be dissolved at neutral pH (> 150 mg/mL), a solution behavior that could not be achieved with wild-type suckerins or SUP lacking the NT and CT domains. In comparison, previous production yields were in the range of 30 mg/L of cell culture, highlighting the efficiency of NT and CT tags not only to enable soluble expression but also to enhance expression yield. As shown by SDS-PAGE (Figure 1c) and MALDI-ToF (Figure 1d) analysis, high purity NT-SUP-CT was obtained after dialysis with the expected molecular weight (MW) of 33.1 kDa. Circular dichroism (CD) spectra (Figure 1e) showed the presence of two minima at 208 and 220 nm at room temperature, which is the signature of α -helices present in the NT and CT tags. At increasing

temperatures, the spectra displayed an upwards shift in the 205-230 nm range, and a smoothing of the two minima at 208 and 220 nm into a broader minimum at 215 nm. These features are characteristic of an α -helix to β -sheet transition of the tag domains upon heating.

We next investigated the behaviour of the suckerin fusion protein in aqueous 20 mM Tris buffer solution at pH 7.4 at a concentration of 3.5 mg/ml by DLS to confirm that NT-SUP-CT proteins are theoretically amenable to the construction of precisely defined nanocapsules by nanoprecipitation. DLS analysis of the aqueous protein solutions is given in Figure 1f and shows two peaks at 9 nm and 50 nm corresponding to free unimers and tiny micellar aggregates of NT-SUP-CT. Importantly, the intensity ratio between the two peaks indicates that under such conditions, most of the proteins present themselves as unimers in the solution, making it ideal to obtain nanocapsules by solvent shifting. As a comparison, wild type suckerins are typically dissolved in an aqueous buffer containing 5% (v/v) acetic acid (pH 3) and DLS analysis of the solution containing 1 mg/ml of suckerin-19 shows two peaks at 30 and 220 nm (data not shown).

The next step consisted in seeking the best nanoprecipitation compositions in phase diagrams. Previously, our group derived the acetone/water/miglyol phase diagram and identified the Ouzo domain.¹³ To find the conditions needed for nanocapsule fabrication, the cloud point boundary of NT-SUP-CT in acetone/aqueous buffer was added here. This limit corresponds to the solubility limit of the protein in the mixture. Its determination method consists in titrating various aqueous solutions of suckerin-silk protein with the organic solvent until the mixtures turns turbid (see experimental part for details). Overlapping the two phase diagrams (see Figure 2a) allows the identification of a solvent shifting domain where, ideally, protein chains and the oil co-precipitate to generate nanocapsules.¹³ The fact that NT-SUP-CT is initially dissolved in Tris buffer (of rather low ionic strength) is not expected to drastically change the boundaries determined here. Inspection of the diagram reveals that the acetone content must be between 30 and 50 wt% for an oil mass fraction of 10^{-4} to prepare nanocapsules inside the ouzo domain. To crosslink the nanocapsules shell, isophorone diisocyanate (IPDI) with a final mass fraction of a 6.5×10^{-6} is also added to the organic phase. The diisocyanate is reactive towards $-NH_2$ and $-OH$ groups available in the protein forming urea and urethane linkages respectively, capable of crosslinking the shells.

At an acetone content of ~ 30 wt%, clean samples of nanocapsules (Figure 2b) with an average diameter $\bar{D}_{Z,DLS}$ around 200 nm ($\bar{D}_{Z,TEM} \sim 190$ nm), a dispersity ($\bar{D}_w/\bar{D}_n$) of 1.35 measured by TEM, and a PDI of 0.10 measured by DLS were obtained. Proteinaceous nanocapsules are in the same size range as some polysaccharide-based nanocapsules but slightly bigger than those typically obtained from glycopolymers chains and miglyol in the Ouzo domain (dimensions below 150 nm). This probably stems from a less favorable stabilization of the oil droplets by the proteins, as suggested by the concomitant observation of few nanoparticles in TEM photos. It is also worth mentioning that contrary to polysaccharide-based nanocapsules, for which $\bar{D}_{Z,DLS}$ and $\bar{D}_{Z,TEM}$ are usually quite different,¹³ these values are very close for NT-SUP-CT-based NCs (200 vs 190 nm), indicating a poor swelling of the suckerin silk membrane in solution.

Note that the interval conditions to prepare nanocapsules is narrow. At an acetone content of 50 wt%, large dark domains were spotted revealing inefficient encapsulation of the oil (see Figure S5a), and the sample could not be analyzed by DLS due to the presence of large protein aggregates (not seen with the naked eye). Decreasing the acetone weight fraction to 40% (Figure S5b) resulted in protein nanoparticles together with nanocapsules. The observed nanocapsules possess a mean diameter of 110 nm as measured by TEM, but DLS analysis did not provide insights into the size distribution due to the presence of large aggregates. Higher acetone content than 30% thus seems to promote a harsh competition between self-aggregation of protein chains and precipitation at the surface of oil droplets. Protein concentration plays an essential role on the control of nanocapsule formation. Figure 2 shows three samples prepared at an acetone content of 30 wt%, a miglyol mass fraction of 10^{-4} and a protein mass fraction of 10^{-5} (Figure 2b), 5×10^{-5} (Figure 2c) and 10^{-4} (Figure 2d). At lower protein concentration the NT-SUP-CT chains seem to preferentially precipitate at the oil droplets surface. Increasing the content of protein five times (Figure 2c) resulted in the formation of protein aggregates together with nanocapsules with a $\bar{D}_{Z,TEM}$ around 185 (STD of 1.35) nm and $\bar{D}_{Z,DLS}$ around 250 nm (PDI of 0.20) (Table 3). At this critical concentration, all oil droplets are encapsulated, and some protein leftovers aggregate together forming the observed dark spots on the TEM image. Further doubling the protein content (Figure 2d) induced the formation of essentially large aggregates.

Nanocapsules were conveniently cross-linked using a 6.5×10^{-6} mass fraction of IPDI. A lower content of IPDI was tested in a trial to optimize the amount of cross-linker used. Figure 2 compares two samples prepared at an acetone content of 30 wt%, a protein mass fraction of 10^{-5} and an oil mass fraction of 10^{-4} cross-linked with 6.5×10^{-6} wt.% (Figure 2b) and 1.6×10^{-6} (Figure 2e). Even though the size and dispersity measured from the dried nanocapsules (TEM) did not change, a higher average diameter size measured by DLS (300 nm) indicates that a lower content of IPDI results in swollen objects and therefore a lower crosslinking density (Table 3). Besides, the background of the TEM images of the samples containing less IPDI appears contaminated, suggesting incomplete crosslinking of the proteins shells and precipitation of the free protein chains upon solvent drying. Most importantly, crosslinking of the protein shell with adequate amounts of IPDI (Table 3b) ensures efficient stabilization of protein-based nanocapsules in aqueous conditions. TEM characterization confirmed that the morphology of the nanocapsules was maintained after evaporation of acetone (Figure S6a). Accordingly, DLS analyses underlined the presence of a main population corresponding to individual nanocapsules (main peak) and a minor population over the μm revealing a little tendency of these objects to aggregate in aqueous solutions (Figure S6b).

The secondary structure of the suckerin-silk chains incorporated in the nanocapsules' shells was further studied by FTIR. Multiple peaks can be assigned to a type of secondary structure, as there may be multiple segments of proteins with the same structural class, thus exhibiting absorption at multiple frequencies (add ref: Byler et al). We have compared amide I bands on the FTIR spectra of the nanocapsule sample after acetone evaporation (Figure 2g) and of the suckerin-silk dissolved in aqueous buffer at a concentration of 0.1 mg/ml (Figure 2f).

Figure 3. Hexadecane droplets encapsulated in NT-SUP-CT shells. **(a)** Phase diagram of the system acetone/water/hexadecane and cloud boundary of NT-SUP-CT. Domain of coprecipitation stained in green. **(b)** TEM image and DLS spectrum of nanocapsules prepared at 30/70 acetone/aqueous buffer ratio, 10^{-5} mass fraction of NT-SUP-CT, 10^{-4} mass fraction of hexadecane and 6.5×10^{-6} mass fraction of IPDI.

When the protein was self-assembled into nanocapsule shells, a clear increase in β -sheet content could be deduced from the increase of the characteristic β -sheet band between 1624 to 1641 nm.³¹ Tests were also performed to investigate the possibility of stabilizing the NT-SUP-CT membranes by triggering the temperature sensitive α -coil – β -sheet transition. A sample prepared with an acetone content of 30 wt%, an oil mass fraction of 10^{-4} and a protein mass fraction of 10^{-5} was heated in a closed vial to 50 °C for 30 min. Unfortunately, this strategy did not seem to successfully freeze the nanocapsules structure, since large protein aggregates were observed by TEM (Figure S8).

Finally, to demonstrate that our approach is not limited to one specific oil and can be generalized to a range of hydrophobic solutes, we further intended to entrap hexadecane nanodroplets into suckerin-silk shells. The hexadecane/acetone/water phase diagram has been previously used by Yan *et al.* to synthesize glyconanocapsules (Figure 3a).¹⁰ Based on our previous investigations with miglyol, we proceeded to the solvent shifting targeting a final acetone content of 30 wt%, 10^{-5} mass fraction of suckerin-silk, 10^{-4} mass fraction of hexadecane and 6.5×10^{-6} mass fraction of IPDI. Similar to the nanoprecipitation system involving miglyol as hydrophobic solute, well-defined oil-filled proteinaceous nanocapsules with an average diameter around 230 nm were conceived in one step (Figures 3b).

In conclusion, the new designed fusion protein suckerin with soluble silk tags exhibits an enhanced solubility in aqueous buffer at a pH (7.4), making it compatible with the nanoprecipitation technique and a good candidate for generating oil-filled protein nanocapsules. In addition, a clear change in solution turbidity can be observed when the aqueous solution of protein is titrated with acetone, which allows the identification of the cloud point boundary and therefore the determination of the domain of composition where oil filled nanocapsules can be generated. IPDI-driven crosslinking was efficient at stabilizing the suckerin-silk shells around the oily cores, with higher concentration of the cross-linker reducing swelling of the shells in the hydrated state. Suckerin-silk-shelled nanocapsules with a mean diameter around 200 nm were fabricated using miglyol or hexadecane as oils. These results validating that NT-SUP-CT fusion proteins show potential to be used in combination with a variety of hydrophobic therapeutics to design proteinaceous nanocapsules by nanoprecipitation form a strong basis for a broad area of applications relying on encapsulation technologies.
